Depressed with cancer can respond to antidepressants, but further research is needed to confirm and expand on these findings

WHAT IS ALREADY KNOWN ON THIS TOPIC?
The quality of life of patients with cancer is affected not only by their physical illness but also by comorbid psychological conditions, such as depression. Mitchell and colleagues reported that major depression has a point prevalence of 10–20% in patients with cancer, irrespective of cancer stage.¹ This prevalence is similar to that seen in patients with other chronic medical illnesses. Both psychological and pharmacological approaches are suggested to be effective for patients with cancer with elevated depressive symptoms.²

WHAT THIS PAPER ADDS
▶ There is very limited evidence to guide the treatment of patients with cancer with a diagnosis of major depression.
▶ In particular, there is very little evidence demonstrating the effectiveness of psychological treatments.
▶ Some evidence exists that antidepressants, alone or in combination with a psychological treatment, may be effective.

LIMITATIONS
▶ The identified studies were too heterogeneous with regard to both the participants and the type of treatments to allow meta-analytical synthesis. The authors were therefore unable to provide informative data for clinicians, including number needed to treat or harm.
▶ Although the present study found several potential biases, including poor allocation concealment (selection bias), unblinded data collection (detection bias) and unspecified primary outcomes (reporting bias) commonly observed in the previous studies, the authors did not provide any clear recommendations for future clinical trials.

WHAT NEXT IN RESEARCH?
▶ Even though there is some evidence that patients with cancer with major depression may respond to antidepressants in general, more data are needed regarding the most commonly prescribed antidepressants (ie, SSRIs and SNRIs), because physicians tend to treat patients with cancer as they treat other depressed patients without comorbidity. Comparative efficacy of antidepressants in the treatment of less severe depression (often occurring in association with advanced disease) are unknown.
▶ Given that patients suffering from clinical depression generally prefer psychological treatments to pharmacological interventions, more studies are needed to investigate the effectiveness of psychological therapies for major depression in patients with cancer.³
▶ In particular, studies of psychological treatments for mild depression in patients with cancer are needed because most depression observed in patients with cancer is generally mild.

DO THESE RESULTS CHANGE YOUR PRACTICES AND WHY?
Since the present study mainly demonstrated the lack of high-quality clinical trials for major depression among patients with cancer, the findings would not influence our current practice. However, it is useful to note that application of unwanted (but received) interventions has been uniquely associated with poor psychosocial adjustment even though the intervention is psychological treatment,⁴ and that we do not know the potential harms of pharmacological treatments especially for patients with cancer with aggressive anticancer treatments and at advanced stages, as shown by the present study. Clinicians should manage major depression among patients with cancer carefully, as efficacy and harms of commonly used treatments remain largely unknown.

REFERENCES

Data sources MEDLINE, EMBASE, PsychINFO and the Cochrane Central Register of Controlled Trials (CENTRAL) from inception to 2012. Study type included RCTs evaluating the efficacy of treatments for depression in adults with a definite cancer diagnosis and a diagnosis of major depression (according to DSM-IV or International Classification of Diseases-10, ICD-10). Intervention Any treatment for depression. Comparison Placebo, standard care or another treatment for depression. OUTCOMES Study characteristics Seven RCTs were identified, including 713 participants. Trials often had unclear risk of bias, and meta-analysis was not possible due to heterogeneity. Results In one trial of women with breast or gynaecological cancer (n=75), mianserin was more effective than placebo in two studies, one lasting 28 days (standardised mean difference (SMD)=0.58, 95% CI 0.13 to 1.05) and other one 42 days (SMD=0.80, 0.26 to 1.34). Another trial in women with breast cancer (n=179) found no significant difference between amitriptyline and paroxetine at 8 weeks. No difference between behavioural activation and problem-solving therapy at up to 12-month follow-up in a trial in women with breast cancer (n=80). Antidepressants treatment combined with education and problem-solving therapy (n=200) was more effective than usual care, (SMD=0.43, 95% CI 0.16 to 0.71).
