Effects of mindfulness-based interventions on alexithymia: a systematic review

Hilary Norman, Lisa Marzano, Mark Coulson, Andrea Oskis

ABSTRACT

Question  Alexithymia has been found to be modifiable through treatment, with associated clinical benefits. Recent studies have begun to test the potential of mindfulness-based interventions to reduce alexithymia, using skills-based, group training to improve non-judgemental, present-moment awareness. The objective of this review therefore was to conduct a systematic synthesis to assess the current state of knowledge about the effect of mindfulness-based interventions on alexithymia to inform clinical practice.

Study selection and analysis  We carried out a systematic review of the literature and found four randomised controlled trials of the effect of mindfulness-based interventions on alexithymia, with a combined total of 460 participants.

Findings  A random-effects meta-analysis, combining study endpoint data, showed a statistically significant effect of mindfulness-based treatment on alexithymia (Toronto Alexithymia Scale) compared with the control group (mean difference=−5.28, 95% CI −9.28 to −1.28, p<0.010). Subgroup analysis was conducted to investigate sources of heterogeneity (I²=52%). Heterogeneity was reduced when the meta-analysis was restricted to interventions of a similar duration (3 months or less).

Conclusions  Findings from our study should be replicated in further research with larger samples; however, the results indicate that mindfulness-based interventions may be an effective treatment in reducing alexithymia.

BACKGROUND

Alexithymia is a trait characterised by difficulties in identifying and communicating emotions, and by an externally orientated thinking style, arising from a deficiency in the neural processing of emotions. Prevalence rates range from 7% to 13% in community samples, but can be several times higher in clinical samples. Alexithymia has been found to be associated with psychological disorders, such as anxiety, depression and general psychopathological distress, and with maladaptive behaviours including alcohol dependence, eating disorders and self-harm. The presence of alexithymia can present a barrier to psychotherapeutic treatment, because the inability of the patient to communicate emotions may induce a negative reaction in the therapist.

There has been a debate as to whether alexithymia is a state-dependent response to trauma or depression or a stable personality trait. The growing consensus is that alexithymia is a trait with relative, rather than absolute, stability, which means that it can be modified through treatment, but that differences between individuals remain largely the same over time. A further consideration is whether any reduction in alexithymia as a result of treatment has any effect on the individual’s health or well-being. There is some indicative evidence that decreases in alexithymia may be beneficial: one study found that reduced alexithymia following therapy was significantly associated with a reduction in cardiac events in patients with coronary heart disease and a second study reported an association between reduced alexithymia and improvements in interpersonal problems. Taken together, this evidence suggests both that it is possible to reduce alexithymia through treatment and also that a reduction in alexithymia may be of positive benefit to the individual. Identifying effective treatment for alexithymia is therefore an important area for further investigation.

A systematic review assessing changes in alexithymia found that studies involving psychological interventions that targeted alexithymic symptoms directly were more likely to report significant reductions in alexithymia than those studies where the intervention was not specifically designed for alexithymia. The interventions that resulted in significant falls in alexithymia tended to use skills-based training designed to increase awareness of bodily sensations and associated emotions. In addition, they often involved group therapy, which may allow alexithymic participants to observe and mirror the way others describe their feelings and experiences. These elements are core to mindfulness-based training courses, such as mindfulness-based stress reduction (MBSR) and mindfulness-based cognitive therapy, in which participants are taught to pay attention to whatever is happening in the present moment, through exercises designed to increase awareness of bodily sensation and non-judgemental observation of thoughts and feelings. Mindfulness-based training has been found to be effective against depression, anxiety and stress in clinical samples and against psychological distress in community samples. Although mindfulness and alexithymia have been shown to be related constructs, with high alexithymia significantly correlated with low levels of mindfulness, Cameron et al’s review did not identify any study that explicitly tested mindfulness-based interventions on alexithymia. However, a small number of studies published since Cameron et al’s review in 2014 indicate that mindfulness-based training might be also effective in reducing alexithymia.
mechanism of enhanced neural processing associated with the identifica-
tion of bodily sensations, termed interoception.30 31

OBJECTIVE
We therefore aimed to carry out a systematic review and meta-
analyses of randomised controlled trials (RCTs) of mindful-
ness-based interventions to provide a quantitative assessment of
the effect of mindfulness-based training on alexithymia.

STUDY SELECTION AND ANALYSIS
The protocol for this systematic review was registered on PROS-
PERO (CRD42017071924).

Search strategy
Electronic databases (PsycINFO, Medline, Web of Science and
Cochrane CENTRAL) were searched from inception until
25 September 2017, using the following terms: ‘affective symp-
toms’ (MeSH) OR ‘alexithymia’ AND mindful AND (interven-
tion* OR random* OR ‘clinical trial’ OR training*). No
restrictions were applied regarding language or date of publica-
tion, but we considered only articles published in peer-reviewed
journals to increase the quality of the included studies. Abstracts
were screened independently by two reviewers and disagree-
ments were solved via discussion with a third member of the
review team. The same two reviewers independently extracted
the data from the included studies.

Study selection
We included only RCTs of any duration comparing mindful-
ness-based interventions with any control condition (phar-
macological or psychological intervention, wait-list, treatment as
usual), in which alexithymia was measured in both the exper-
imental and control groups, using a validated measure. To be
included, mindfulness training had to be a component or the
whole of the intervention. No exclusion criteria were set
regarding age, diagnosis or other participant demographics.

Outcomes
The primary outcome was the severity of alexithymia symp-
toms at study endpoint. We also carried out secondary anal-
yses of severity of alexithymia symptoms within 3 months. We
decided to choose this time point because it is common to the
included studies and is closest to the standard length of an MBSR
programme.38 All four studies measured alexithymia, using the T oronto
Alexithymia Scale (TAS20).1 In one study, 35 mindfulness
training had to be a component or the whole of the inter-
vention.38 All four studies measured alexithymia,

Data extraction
Data from the studies were extracted using a standardised form.
Extracted information included study sample characteristics,
details of the intervention (such as duration, activities under-
taken and method of delivery and number), severity of symp-
toms and timings of measurement.

Risk of bias assessment
The risk of bias was assessed using the Cochrane tool as reported
in the Cochrane handbook.32 This enables researchers to assess
as high, low or unclear seven different types of risk that might
cause the effect of treatment in individual studies to be overesti-
mated or underestimated. Risk of bias assessment was carried out
independently by two reviewers and any disagreement resolved
through consensus or by discussion with another member of the
review team.

Statistical analysis
As our outcomes were continuous, we calculated the pooled
mean difference (MD) with corresponding 95% CIs, as appro-
priate. We considered a p value of less than 0.05 and a 95%CI
that does not cross the line of no effect as statistically signifi-
cant. The standardised mean difference (SMD) was also calcu-
lated as a measure of the effect size. In accordance with the study
protocol, we used a random-effects model because it has the
highest generalisability for empirical examination of summary

effect measures in meta-analyses.33 However, as recommended
by the Cochrane Handbook for Systematic Reviews of Interven-
tions34 (10.4.4.1) when concerned about the influence of small
study effects on the results of a meta-analysis with between-study
heterogeneity, we examined the robustness by comparing the
fixed-effect model and the random-effects model. We reported
any material differences between the models. In the case that
a study included multiple intervention cohorts, we decided to
combine the outcome data from all the intervention cohorts,
using the method recommended by Higgins and Green.32 We
planned to conduct subgroup analyses if there were large differ-
ences between the interventions or between participant charac-
teristics. All analyses were carried out using RevMan V.5.3.34

FINDINGS
In total, 116 articles were retrieved from the database search,
which resulted in 59 individual studies after duplicates were
removed (figure 1). After screening, a total of four studies met
the criteria, all published since 2010, with a combined total
sample of 460 participants.35–38 A full description of the four
studies is given in table 1.

Sixty-five per cent of the total sample was female. The mean
age ranged from 23.5 to 53.8, with one study restricting the age
range of eligible participants to between 20 and 55.36 Three
studies were from non-clinical samples35–37 and two studies35 37
additionally included individuals in poor psychological health.
Participants in the fourth study were women with symptoms of
burnout or exhaustion.38 Three of the studies explicitly excluded
people with prior experience of meditation.35–37

Two studies compared mindfulness-based interventions based
on the MBSR programme, delivered over 8 weeks37 and 10
weeks,36 with wait-list. A third study tested a bespoke mind-
fulness-based programme of contemplative mental training
delivered in three different 3-month modules.35 In this study,
two intervention cohorts participated in all three modules in a
different order, one intervention cohort only took one 3-month
module and a control group had no training. Finally, the fourth
study tested a 3-month package of six different cultural activi-
ties (including mindfulness training, and also dance, theatre and
art).38 This was compared with standard care, consisting of phys-
iotherapy and light physical exercise. This was the only study to
include a follow-up assessment at 6 months, 3 months after the
end of the intervention.38 All four studies measured alexithymia
using the Toronto Alexithymia Scale (TAS20).1 In one study,35
individuals with a TAS20 score of over 60 were excluded. Other
variables measured are described in table 1. Only one study35
measured mindfulness, using the Mindful Attention Awareness
Scale (MAAS).39

The assessment of risk of bias is set out in figure 2. The main
risk of bias was considered to be in the blinding of outcome
assessment, which is difficult to achieve with a self-report
outcome measure.

A random-effects meta-analysis was carried out to assess mean
difference in TAS20 scores between the experimental and control

Evd Based Mental Health: first published as 10.1136/ebmental-2018-300029 on 4 August 2018. Downloaded from http://ebmh.bmj.com/ on August 12, 2021 by guest. Protected by copyright.
groups at study endpoint. Study endpoint was interpreted as the final data collection. In two studies, the study endpoint coincided with the end of treatment for all participants.\(^{36,37}\) In Bornemann and Singer,\(^{35}\) data from the three experimental cohorts at the end of their respective treatment periods were combined. In the case of Viding et al.,\(^{38}\) the study endpoint occurred at the 6-month follow-up assessment. In order to make use of all the available evidence, subgroup analyses were carried out to assess mean difference in TAS20 scores between the experimental and control groups at different time points post baseline: at T\(_1\) (within 3 months post baseline), T\(_2\) (6 months post baseline) and T\(_3\) (9 months post baseline). The results are set out in Figure 3.

Combining the results from all studies at study endpoint resulted in a significant model (MD\(=−5.28, 95\%\ CI −9.28\) to \(−1.28, p=0.010, 435\) participants). This difference corresponded to a SMD of \(−0.48\), indicating a moderate effect size (Figure 3), but the heterogeneity between the studies was moderate to high (I\(^2\)=52\%). At T\(_1\), the results from the four studies show that although alexithymia levels were lower in the experimental group than the control group, the overall effect of treatment was not significant, with significant heterogeneity (MD\(=−4.59, 95\%\ CI −9.31\) to \(−1.28, p=0.010, 435\) participants). Excluding Bornemann and Singer,\(^{35}\) on the grounds that the intervention was not complete for most participants at T\(_1\), produced a significant model (MD\(=−6.91, 95\%\ CI −11.52\) to \(−2.30, p=0.003, 134\) participants), and reduced heterogeneity to I\(^2\)=64\% (441 participants). The difference between experimental and control groups at T\(_1\), based on two studies, was not significant (MD\(=−3.04, 95\%\ CI −7.24\) to \(1.16, p=0.16, 276\) participants). Finally, Bornemann and Singer,\(^{35}\) the only study to take measurements at T\(_3\), reported a significant difference between the experimental and control groups at that time point (MD\(=−2.84, 95\%\ CI −5.30\) to \(−0.38, p=0.02, 226\) participants).

One possible cause of heterogeneity is the difference between the interventions. While three of the interventions tested centred on mindfulness-based training, in Viding et al.\(^{38}\) the mindfulness element accounted for only one-sixth of the total intervention. A sensitivity analysis was conducted on the primary outcome of mean alexithymia at study endpoint, excluding Viding et al.\(^{38}\) This exclusion increased the heterogeneity of the model, but it remained significant (I\(^2\)=65\%, MD\(=−4.99, 95\%\ CI −9.84\) to \(−0.13, p=0.04, 389\) participants).

Finally, for comparison purposes, a fixed-effects meta-analysis was carried out on the primary outcome of the mean difference in TAS20 scores between the experimental and control groups at study endpoint (Figure 4). This resulted in a significant model (MD\(=−4.00, 95\%\ CI −6.00\) to \(−1.99, p<0.0001, I^2=52\%, 435\) participants).

**CONCLUSIONS AND CLINICAL IMPLICATIONS**

This systematic review and meta-analysis examined the effect of mindfulness-based interventions on alexithymia. The combined results from the four RCTs found in the literature indicate that mindfulness-based interventions significantly reduce alexithymia, compared with a control condition, at the end of the study period. It is not clear if the observed effect can last beyond 9 months (i.e., the length of the longest intervention in the included trials).

**Nature of the intervention**

The studies differed in the length of the intervention offered, with Bornemann and Singer’s\(^{35}\) 9-month programme considerably...

longer than the interventions tested in the other studies and also the conventional length of a MBSR programme. However, excluding Bornemann and Singer's study from the meta-analysis of outcomes at 3 months, on the grounds that the intervention was not complete for most participants at that point, produced a significant effect of mindfulness-based training, suggesting that it is the content of the intervention rather than its length that is important for alexithymia. This is in line with non-randomised evidence, which suggests that even a short intervention can have a positive effect. Byrne et al. tested a 2-week mindfulness-based intervention on a group of sex offenders in prison and found that alexithymia decreased significantly in the intervention group compared with the control group over the short period of the intervention.

**Mechanisms**

The intervention tested by Bornemann and Singer gives an opportunity to deconstruct the elements of a mindfulness-based intervention since it was explicitly divided into three modules covering awareness of the present moment and particularly of bodily sensations (Presence), accepting difficult emotions with loving kindness (Affect) and observing thoughts and learning reappraisal skills (Perspective). The authors found that a significant decrease in alexithymia was attributable only to the Presence and Affect modules, and not to the Perspective module. The mindfulness-based class that formed part of the intervention tested in Viding et al. would appear to be similar in content to the Presence module in Bornemann and Singer’s study, as it was focused on breathing and awareness of the body, thoughts and feelings. Taken together, these studies may indicate that increased awareness of present experience, particularly awareness of bodily sensations, may be one mechanism by which alexithymia is reduced. Alexithymia (awareness of emotional experience) has been found to be strongly related to interoception (awareness of bodily experience) and improvement in alexithymia symptoms has been associated with increased heartbeat perception accuracy. Furthermore, Santarnecchi et al. reported a significant correlation between the decrease in alexithymia and an increase in right insula thickness, an area of the brain, which is involved in both emotional and bodily awareness. Interestingly, however, Bornemann and Singer found that the significant correlation between the decrease in alexithymia and increased heartbeat awareness was only observed among those who had taken part in the Presence training module and not among those who had taken the Affect training module. The authors conclude that the significant decrease in alexithymia observed among participants in the Presence module may be attributable to an increase in interoception, but that reduction in alexithymia in participants in the Affect module, which focused on the acceptance of difficult emotions, may be attributable to a different mechanism.

It might be assumed that another mechanism by which alexithymia is reduced following mindfulness-based training is an increase in trait mindfulness. In fact, the only one of the four studies included in this review to measure trait mindfulness reported no significant change in mindfulness as a result of the intervention, a surprising finding that runs counter to other evidence. The authors attribute this result to the use of the MAAS. The items in the MAAS focus on the respondent’s ability to pay attention to what is happening in the present moment (eg, “I drive places on automatic pilot and then wonder why I went there”) rather than the emotional and non-judgemental aspect of mindfulness captured in other measures. This conception of mindfulness, which places little emphasis on identifying or describing feelings, might explain the lower correlations between the MAAS and the TAS20 than between the TAS20 and other measures of mindfulness, such as the Kentucky Inventory of Mindfulness Skills and the Five Facet Mindfulness Questionnaire. Santarnecchi et al.’s findings might imply that the mechanism of change through which mindfulness-based interventions operate on trait mindfulness and alexithymia is not based on the attentional aspect of mindfulness, but more research and larger study samples are needed to test this hypothesis further.

Comparison with other interventions

One question that arises from the results of this review is how a combined mean difference of five points on the TAS20 scale between intervention and control groups post mindfulness-based training compares with the effect of other types of intervention on alexithymia. There is some evidence from uncontrolled pre–post studies to support the use of other therapies in treating alexithymia, including cognitive behavioural therapy (CBT),\textsuperscript{44,45} psychodynamic group therapy\textsuperscript{7} and voice movement therapy.\textsuperscript{46}

An RCT comparing the effect of a psychoeducation and cognitive restructuring programme for patients with cancer with standard medical care resulted in a much greater difference in mean TAS20 between the groups after treatment than found in the current meta-analysis (MD=−17.29, CI −22.52 to −12.06).\textsuperscript{17}

However, the difference was due in large part to a significant increase in TAS20 in the control group, which may be a specific

Clinical implications

This review has identified a statistically significant effect of mindfulness-based interventions on alexithymia. It is worth noting that in all the studies, the baseline level of alexithymia was relatively low and below the clinical threshold.25 It is possible that the effect of a mindfulness-based intervention might be still greater in clinical populations where baseline alexithymia may be higher.38 Bornemann and Singer35 observed larger falls in TAS20 scores among those who had higher alexithymia at baseline (above 51) than those with low alexithymia.

Alexithymia has been described as a transdiagnostic factor associated with a range of disorders.19 Using mindfulness-based training to reduce alexithymia might therefore be a means of improving the efficacy of subsequent condition-specific treatments. An increased awareness of, and ability to talk about, emotions might, for example, enable better engagement with psychotherapy.12 More evidence is needed to establish whether a reduction in alexithymia is directly and causally related to improvements in health. The studies reviewed here reported significant improvements post intervention in some measures of psychological health (eg, worry, anxiety and depression37; exhaustion and self-reported health38) but not others (eg, sense of coherence38). Where improvements were observed, it is not possible to say whether they are related to the changes in alexithymia or merely concurrent. Further research is needed, particularly to test the implications of a decrease in alexithymia on psychological health.

As far as non-clinical populations are concerned, mindfulness-based interventions may be effective in reducing alexithymia as a preventative measure. One advantage of mindfulness-based interventions is that they can be delivered in community settings and are becoming increasingly popular as a means of reducing stress.25 High alexithymia per se is unlikely to be an explicit reason someone might seek treatment but is rather a comorbid, and potentially causal, feature of many other presenting behaviours or psychological features.47 Community-based, universal interventions, therefore, may be a means of preventing future problems by improving alexithymic symptoms.

Limitations

There were several limitations in this review. First, the conclusions are based on a combined sample size of just 460 participants. We focused only on RCTs, excluding other, non-randomised and uncontrolled trials of the effect of mindfulness-based interventions on alexithymia. Although this limited the number of included studies to four, it meant that the conclusions were based on the highest quality evidence available. Second, the heterogeneity between the studies was found to be moderate to high. We conducted sensitivity analysis to assess whether this was due to the differences in either the content or the length of the interventions. The results showed that heterogeneity was higher when studies with interventions of different lengths were combined. It should be noted, however, that the only study that tested an intervention of over 3 months’ duration19 accounted for nearly 70% of the combined sample. The observed heterogeneity, therefore, may be due to the inclusion of studies with small sample sizes in the meta-analysis.50 Future RCTs with larger samples could usefully explore further whether the content or the duration of an intervention affects the outcome.

A third limitation is the absence of an active control group. A meta-analysis of mindfulness-based therapy found no significant difference in outcomes between mindfulness therapy and other therapeutic interventions such as CBT.24 None of the studies in the current review included an active control group, which would have allowed the effect of mindfulness-based interventions to be compared with other types of active treatment. However, Bornemann and Singer35 found that two of their training modules resulted in reduced alexithymia, while the third, which focused on observing thoughts and learning reappraisal skills, did not. This finding appears to suggest the reduction in alexithymia is attributable to the content of that particular training module, rather than other aspects of the intervention such as the method of delivery.

Finally, while two of the interventions were based on the MBSR programme,36 37 two tested bespoke interventions,35 38 which may limit the conclusions that can be drawn for clinical practice. In one of these studies38 mindfulness training comprised only one-sixth of the intervention, and therefore it is not possible to attribute the effect of the intervention to the mindfulness component with any certainty. To address this limitation, we conducted subgroup analysis excluding this study and found that the model remained significant, although the heterogeneity increased.

CONCLUSIONS

Participation in mindfulness-based interventions led to significantly lower alexithymia at the study end compared with a control group. The literature on which these conclusions are based is limited, and further RCTs with larger clinical and non-clinical samples and longer follow-up are required. However, the findings indicate that mindfulness-based interventions may be an effective means of reducing alexithymia.

Compliance with ethical standards

Research involving human or animal participants: This article does not contain any studies with human participants or animals performed by any of the authors.
