Increased risk of Alzheimer’s disease in mothers who gave birth to children with Down’s syndrome before 35 years of age

QUESTION: Are mothers who give birth to children with Down’s syndrome (DS) before the age of 35 years at increased risk of neurological or medical disorders?

Design
Cohort study.

Setting
Community based study in the 9 county downstate region of New York, USA.

Participants
A random sample of parents (n=395) of 200 adults who were 30–70 years of age and had DS, and matched group of parents (n=495) of 252 adults with other forms of mental retardation (control group) were identified from the New York State Office of Mental Retardation and Developmental Disabilities registry.

Assessment of risk factors
Parents’ age at birth of children with DS or other forms of mental retardation and parents’ medical history were obtained by interview with parents and other first degree relatives.

Main outcome measures
Diagnosis of Alzheimer’s disease (AD), other dementias, and age related disorders in the parents.

Main results
Mothers who were ≤ 35 years of age when their children with DS were born were 4–5 times as likely to develop AD as control mothers (table). The risk of AD among mothers who were > 35 years of age when their children with DS were born was not statistically increased (table). Risk of AD among fathers of children with DS was similar to that of the control fathers, and did not vary by age at the child’s birth (table). Risk of other dementias and of other age related medical conditions were similar among mothers and fathers of children with DS and control parents regardless of age at the child’s birth.

Conclusion
There was an increased risk of Alzheimer’s disease in mothers who gave birth to children with Down’s syndrome before the age of 35 years.

COMMENTARY

So does DS lead to AD, or does a risk factor for AD in women lead to increased risk of DS? One of the important proteins in AD pathogenesis is amyloid precursor protein (APP) coded on chromosome 21.1 Mutations in this gene lead to early AD, but they are thought to be very rare (only 29 pedigree families known). However, the presence of an extra chromosome 21 in DS leads to a much increased incidence of AD in this group (50% of those who reach 50 y of age). This has been assumed to be due to the extra chromosome causing a 50% increase in amyloid production, which basically overburdens the clearance system. But 2 other scenarios could now be postulated. Maybe an APP defect exists on chromosome 21 that alone can increase late onset AD rates in the parent, but is passed on twice when trisomy or translocation occurs, producing higher AD rates in DS – by mimicking autosomal dominant transmission. Alternatively, an APP defect may interfere with meiosis, increasing the risk of non-disjunction and hence DS. 95% of DS trisomies are due to maternal non-disjunction;1 and although trisomy increases with age, a genetic susceptibility to translocation is believed more common in younger parents, accounting for the difference below 35 years. Obviously, cause and effect cannot be drawn from this well presented data. However, the fact that a genetic and molecular link is known to occur in these disorders, plus this apparent 5-fold increase in AD incidence in the mothers of DS, suggests new research avenues. Early presenting amyloidopathies of the brain have been proven to be due to several genetic mutations, and this finding in the mothers of DS children implies that their chromosome 21 could hold more clues that may help unlock both these tragic disorders.
